Forms and Function of Plants and Animals

PHOTOSYNTHESIS

Photosynthesis (Photo = light; synthesis = to join) is the single most important process on earth on which depends the existence of human and almost all other living organisms. It is a process by which green plants, algae and chlorophyll containing bacteria utilize the energy of sunlight to synthesize their own food (organic matters) from simple inorganic molecules. Innumerable number of organic molecules which compose the living world are derived directly or indirectly from the photosynthetic organic matter. The oxidation of organic compounds releases stored energy to be utilized by the organism to carry out essential metabolic processes. It is important to note that photosynthesis is the only natural process which liberates oxygen to be used by all living forms for the process of respiration.

You have studied in lesson 4, that chloroplasts are the organelles that carry out photosynthesis or in other words they act as solar cells producing carbohydrates. In this lesson you will learn how plants carry out photosynthesis.

After completing this lesson, you will be able to:

- define photosynthesis;
- name the different pigments found in chloroplasts and describe the ultra structure of chloroplasts with a diagram;
- explain the main aspects of the process of photosynthesis;
- enumerate the steps involved in the light and dark reactions of photosynthesis;
- define the terms absorption spectrum, electron acceptor, photophosphorylation and action spectrum;
- distinguish between, absorption spectrum and action spectrum; light and dark reactions, cyclic and non-cyclic phosphorylation, C_3 and C_4 photosynthesis;
- list the environmental variables and internal factors affecting photosynthesis;
- describe the principle of limiting factor giving suitable graphs.

rms and Function of ints and Animals

Photosynthesis

11.1 PHOTOSYNTHESIS

11.1 Let us look into the significance of the process

Significance

- 1. Green plants possess the green pigment, chlorophyll which can capture, transform, translocate and store energy which is readily available for all forms of life on this planet.
- 2. Photosynthesis is a process in which light energy is converted into chemical energy.
- 3. Except green plants no other organism can directly utilise solar energy, hence they are dependent on green pants for their survival.
- 4. Green plants can prepare organic food from simple inorganic elements (autotrophic) while all other organisms cannot prepare their own food and are called heterotrophic.
- 5. During photosynthesis, oxygen liberated into the atmosphere makes the environment livable for all other organisms.
- 6. Simple carbohydrates produced in photosynthesis are transformed into lipids, proteins, nucleic acids and other organic molecules.
- 7. Plants and plant products are the major food sources of almost all other organisms of the earth.
- 8. Fossil fuels like coal, gas, oil etc represent the photosynthetic products of the plants belonging to early geological periods.

11.1.1 What is photosynthesis?

Photosynthesis (photo-light; synthesis-to put together) is the process by which green plants, in the presence of light combine water and carbon dioxide to form carbohydrates, oxygen is released as a by product. Current knowledge of photosynthesis has resulted from discoveries made over 300 years of work. Some landmark experiments are given in the box below.

- Joseph Priestly and later Jan Ingenhousz showed that plants have the ability to take up CO_2 from the atmosphere and release O_2 .
- Ingenhousz also discovered that release of O_2 by plants was possible only in presence of sunlight and by the green parts of the plant.
- Robert Hill demonstrated that isolated chloroplasts evolve O₂ when they are illuminated in the presence of electron acceptor which get reduced. This reaction called Hill reaction accounts for the (break down) use of water (photolysis) as a source of electrons for CO₂ fixation and release of O₂ as by-product.

Photosynthesis is represented by the following overall chemical equation:

$$6\text{CO}_2 + 12\text{H}_2\text{O} \xrightarrow{\text{Chlorophyll}} \text{C}_6\text{H}_{12}\text{O}_6 + 6\text{H}_2\text{O} + 6\text{O}_2$$

In photosynthesis CO_2 is fixed (or reduced) to carbohydrates (glucose $C_6H_{12}O_6$). Water is split in the presence of light (called photolysis of water) to release O_2 . Note that O_2 released comes from the water molecule and not from CO_2 .

11.1.2 Where does photosynthesis occur?

Photosynthesis occurs in green parts of the plant, mostly the leaves, sometimes the green stems and floral buds. The leaves contain specialised cells called mesophyll cells which contain the chloroplast the pigment containing organelle. These are the actual sites for photosynthesis.

Look at the figure 11.1 to recollect what you learnt about the structure of chloroplast in the lesson-4 Cell Structure and Function.

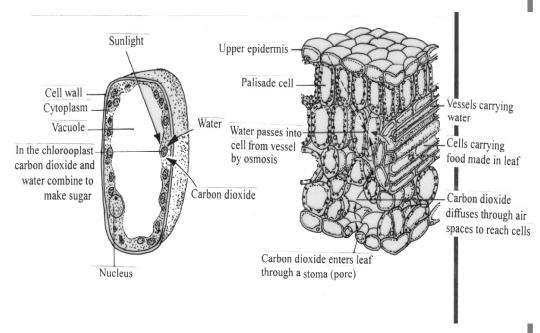

Fig. 11.1 Structure of chloroplast

11.2 PHOTOSYNTHETIC PIGMENTS

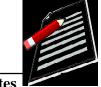

The thylakoids of the chloroplast contain the pigments which absorb light of different wave length and carry out the photochemical reaction of photosynthesis.

The role of the pigments is to absorb light energy, thereby converting it to chemical energy. These pigments are located on the thylakoid membranes and the chloroplasts are usually so arranged within the cells that the membranes are at right angles to the light source for maximum absorption. The photosynthetic pigments of higher plants fall into two classes the chlorophyll and carotenoids.

The photosynthetic pigment **chlorophyll** is the principle pigment involved in photosynthesis. It is a large molecule and absorbs light in the violet blue and in the red region of the visible spectrum and reflects green light and thus leaves appear green in colour. **Carotenoids** (carotene and xanthophyll) absorb light in the regions of the spectrum not absorbed by the chlorophyll.

MODULE - 2

Forms and Function of Plants and Animals

Notes

rms and Function of ints and Animals

6

Photosynthesis

Chlorophyll a (a special type of chlorophyll) is the main pigment that traps solar energy and converts it into electrical and chemical energy. Thus it is called the **reaction centre.**

All other pigment such as chlorophyll b and carotenoids are called accessory pigments since they pass on the absorbed energy to chlorophyll a (Chl.a) molecule. These pigments, that is the reaction centres (Chl. a) and the accessory pigments (harvesting centre) are packed into functional clusters called photosystems. Photosystems are of two types PSI and PSII.

About 250-400 pigment molecules constitute a single photosystem. Two different photosystems contain different forms of chlorophyll a in their reaction centres. In photosystem I (PSI), chlorophyll a with maximum absorption at 700 nm (P700) and in photosystem II (PSII), chlorophyll a with peak absorption at 680 nm (P_{680}), act as reaction centres. (P stands for pigment). The primary function of the two photosystems, which interact with each other is to trap the solar energy and convert into the chemical energy (ATP). The differences between them are given in the following table 11.1.

Table 11.1 Difference between Photosystem I and Photosystem II

Photosystem I	Photosystem II
PS I has a reaction centre of chlorophyll 'a' molecule with maximum light absorption at 700 nm wavelength. This reaction centre is also referred to as P ₇₀₀ .	PS II has a reaction centre of chlorophyll 'a' molecule with maximum light absorption at 680 nm. This reaction centre is also referred to to as P_{680} .
Primary electron acceptor is an iron protein (Fe-Sprotein)	Primary electron acceptor in a colourless less chlorophyll a that lacks magnesium (Mg) and is known as phaeophyll a.
A set of electron carriers the plastocyanin, ferredoxin and cytochrome	A set of electron carriers the phaeophytin plastoquinone, cytochromes.

11.3 ROLE OF SUNLIGHT IN PHOTOSYNTHESIS

Light consists of small particles or packages of energy called "photons". A single photon is also called **quantum.** What does the chlorophyll do? It absorbs light energy.

Chlorophyll molecules absorb light energy and get into an excited state and lose an electron to the outer orbit. No substance can remain in an excited state for long, so the energised and excited chlorophyll molecule comes down to a low energy state known as **ground state** and release the extra amount of energy. This energy can be lost as heat, or as light (flourescence) or can do some work. If photosynthesis, it works by splitting water moelcule to produce H⁺ and OH⁻ ions.

Carotene is orange-yellow pigment present along with chlorophylls in the thylakoid membrane. A carotene molecule breaks down into the vitamin A molecules. It is this pigment which gives carrot its colour.

Absorption and Action Spectra

For investigating a process such as photosynthesis that is activated by light, it is important to establish the action spectrum for the process and to use this to identify the pigments involved. An action spectrum is a graph showing the effectiveness of different wavelengths (VIBGYOR) of light in stimulating the process of photosynthesis, where the response could be measured in terms of oxygen produced at different wavelengths of light. An **absorption spectrum** is a graph of the relative absorbance of different wavelengths of light by a pigment. An action spectrum for photosynthesis is shown in Fig. 11.2 together with an absorption spectrum for the combined photosynthetic pigments. Note the close similarity, which indicates that the pigments, chlorophyll in particular, are responsible for absorption of light in photosynthesis.

All wavelengths of light are not equally effective in photosynthesis i.e. the rate of photosynthesis is more in some and less in others.

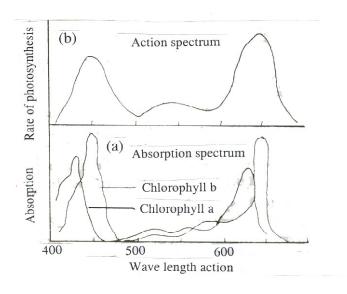

Fig. 11.2 Spectra of electromagnetic radiation B. Action Spectrum

Photosynthesis is very little in green and yellow light, because these rays are reflected back from the leaf. Photosynthesis is maximum in blue and red light.

		Photosynthesis			
	(ii)	Give the overall general chemical equation of photosynthesis.			
2.	(i)	List the two categories of photosynthetic pigments.			
	(ii)	Which pigments are known as accessory pigments?			
3.	(i)	What does chlorophyll do to the light falling on it?			
	(ii)	Which pigment system absorbs the red wavelength of light?			
4.	Answer the following				
	(i)	In which colour of light, rate of photosynthesis is minimum and in which colour of light it is maximum?			
	(ii)	Name the type of energy that is used in the process of photosynthesis. In which form does this energy get stored in plant body?			
5.	Which	th molecule is the source of evolution of oxygen in photosyntheisis— CO_2 O?			

11.4 PHOTOCHEMICAL AND BIOSYNTHETIC PHASE

- The entire process of photosynthesis takes place inside the chloroplast. The structure of chloroplast is such that the light dependent (**light reaction**) and light independent (**Dark reaction**) take place at different sites in the organelle.
- The thylakoids have the pigments and other necessary components to absorb light and transfer electrons to carry out the light reaction or Electron Transport Chain (ETC). In ETC upon absorption of light, the electrons from PSII and PSI are boosted to a higher energy level i.e. the electrons acquire excitation energy. As the electrons gain this energy, they are accepted by the electron acceptor which in turn is reduced, leaving the reaction centres of PSII and PSI i.e. P₆₈₀ and P₇₀₀ molecules in an oxidised state. This represents the conversion of light energy into chemical energy. The electrons then travel downhill in energy terms, from one electron acceptor to another in a series of oxidation reduction reaction. This electron flow is 'coupled' to the formation of ATP. In addition, NADP is reduced to NADPH₂. The products of light reaction called the reducing power (ATP and NADPH₂) move out of the thylakoid into the stroma of the chloroplast.
- In the stroma goes on the second step (**dark reaction or biosynthetic pathway**) where CO₂ is reduced by the reducing power generated in the first step and carbohydrates are produced.

Let us study these two steps in some more detail in the next part of the lesson.

11.4.1 Electron transport chain in photosynthesis

It starts as the PSII absorbs light energy and passes it on to its reaction centre, P₆₈₀. When P_{680} absorbs light, it is excited and its electrons are transferred to an electron acceptor molecule (Primary electron acceptor) and it itself comes to the ground state. However by losing an electron P₆₈₀ is oxidised and in turn it splits water molecule to release O_2 . This light dependent splitting of water is called **photolysis**. With the breakdown of water electrons are generated, which are then passed on to the electron deficient P₆₈₀ (which had transferred its electrons earlier). Thus the oxidised P₆₈₀ regains its lost electrons from water molecules.

The reduced primary acceptor now donates electrons to the down stream components of the electron transport chain. The electrons are finally passed onto the reaction centre P₇₀₀ of PSI. During this process, energy is released and stored in the form of ATP.

Similarly, PSI also gets excited when it absorbs light and P₇₀₀ (Reaction centre of PSI) gets oxidised as it transfers its electrons to another primary acceptor molecule. While the oxidised P_{700} draws its electrons from PSII, the reduced primary acceptors molecule of PSI transfers its electrons via other electron carrier to NADP (Nicotinamide Adenine Dinucleotide Phosphate) to produce NADPH₂ a strong reducing agent. Thus we see that there is a continuous flow of electrons from the H₂O molecules to PSII to PSI, and finally to the NADP molecule which is reduced to NADPH₂. NADPH₂ is then utilised in reduction of CO₂ to carbohydrates in the biosynthetic path way.

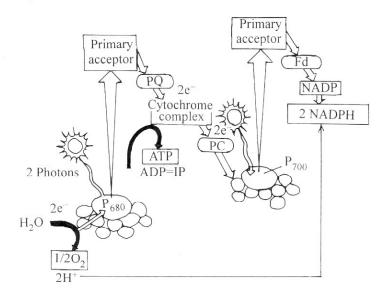

Fig. 11.3 Non-cyclic photophosphorylation PQ = Plastoquinine, PC-Plastocyanin Fd= Ferrsdoxin

Reduction of CO₂ to carbohydrate also requires ATP which too are generated via electron transport chain. As the energy rich electrons pass down the electron transport system, it releases energy which is sufficient to bind inorganic phosphate (Pi) with ADP to form ATP. This process is called phosphorylation.

MODULE - 2

Forms and Function of Plants and Animals

Notes

rms and Function of ants and Animals

Photosynthesis

Since this takes place in presence of light it is called **Photo phosphorylation.** It occurs in chloroplast in two ways:

- (a) Non-cyclic photophosphorylation where electrons flow from water molecule to PSII and then to PSI and ultimately reduce NADP to NADPH₂. since the electrons flow in unidirection it is called non cyclic photosphorylation (Fig. 11.3).
- (b) Cyclic photophosphorylation under certain condition when non-cyclic photophosphorylation stops, cyclic photophosphorylation occurs and it involves PSI only. During this process electrons from PSI are not passed on to NADP. Instead the electrons are returned to the oxidised P_{700} molecule. This downhill movement of electrons results in ATP formation. Thus this is termed as cyclic photophosphorylation (Fig. 11.4).

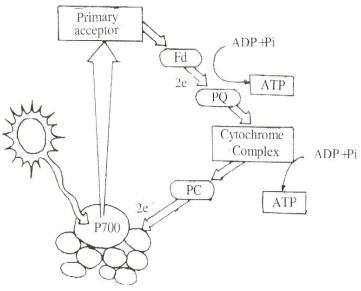

Fig. 11.4 Cyclic photophosphorylation

Table 11.2 Differences between cyclic and non-cyclic photophosphorylation

	Cyclic photophosphosylation	Non-cyclic photophosphorylation
1.	Only PSI in functional.	1. Both PSI and PSII are functional.
2.	Electron comes from the chlorophyll molecule and returns to the chlorophyll	2. Water is the source of the electorns and NADP is the final acceptor of the electron. The electron goes out the system.
3.	Reduced NADP (NADPH $_2$) is not formed.	3. Reduced NADP i.e., NADPH ₂ is formed which is used in the reduction of carbondioxide.
4.	Oxygen is not evolved	4. Oxygen is evolved as a by product.
5.	This process is formed mainly in photosynthetic bneteria.	5. This mainly takes place in green plants.

Extra ATP can be made via cyclic photophosphorylation. The efficiency of energy conversion in the light reactions is high and estimated at about 39%.

11.5 BIOSYNTHETIC PATHWAY (DARK REACTION)

- Both NADPH₂ and ATP produced during light reaction are essential requirements for synthesis of carbohydrates.
- These series of reaction which catalyse the reduction of CO₂ to carbohydrates (also called fixation of CO₂) take place in the **stroma** of the chloroplast.
- These reactions are independent of light i.e. light is not necessary but can continue in light as well. Thus it is also called dark reaction.
- The carbon fixation reactions produce sugar in the leaves of the plant from where it is exported to other tissues of the plant as source of both organic molecule and energy for growth and metabolism.
- There are **two** major pathways by which CO₂ fixation (Dark reaction) takes place.

11.5.1 C₃ cycle (also called Calvin cycle after its discoverer, Melvin Calvin)

In this cycle, initially the atmospheric CO_2 is accepted by a 5-carbon sugar ribulose bisphosphate (RuBP) and two molecules of 3-carbon compound, 3-phosphoglyceric acid (PGA) are formed. This 3-carbon molecule is the first stable product of this pathway and hence the name C₃ cycle. Formation of PGA is called carboxylation. This reaction is catalysed by an enzyme called ribulose bisphosphate **carboxylase Ru bisco.** This enzyme is probably the most abundant protein on earth.

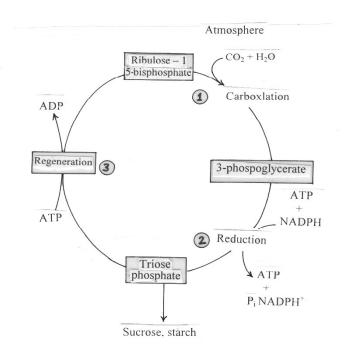

Fig. 11.5 The Calvin cycle

MODULE - 2

Forms and Function of Plants and Animals

Notes

rms and Function of ints and Animals

Photosynthesis

- In the next step, PGA is reduced to 3-carbon carbohydrate called **triose phosphate** using NADPH₂ and ATP (from light reaction). Much of these molecules are then diverted from the C₃ cycle and used for synthesis of other carbohydrates such as glucose and sucrose.
- To complete the cycle, the initial 5-carbon acceptor molecule, RuBP is regenerated from the triose phosphates using ATP molecule thus the C_3 cycle continues of C_3 cycle.

11.5.2 C₄ Cycle (or Hatch and Slack Cycle)

- The C_4 cycle seems to be an adaptation for plants growing under dry hot environment. Such plants can photosynthesise even in the conditions of very low CO_2 concentration and under partial closure of stomata.
- Such plants can thus grow at low water content, high temperature and high light intensity. Sugar cane, maize are some such plants.
- Photorespiration (oxidation of RuBP in presence of O₂) is absent in these plants. So the photosynthetic rate is high. (For detail of photorespiration refer to lesson-12 Plant Respiration Section No. 12.5)
- The leaves of C₄ plants show special anatomy called **Kranz anatomy**. These are :
 - (a) The vascular bundles have a sheath of large parenchyma cells around them in the form of a wreath thus the name Kranz anatomy (Kranz : wreath)
 - (b) Leaves possess two types of chloroplasts (dimorphic chloroplasts)
 - (c) Chloroplasts in the mesophyll cells are smaller and have well developed grana but do not accumulate starch.
 - (d) Chloroplasts in the bundle sheath cells are larger and lack grana (agranal chloroplasts) but contain numerous starch grains. (See Fig. 11.6).

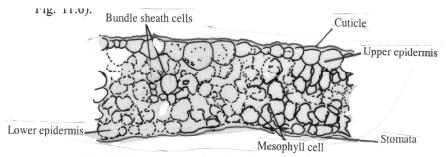

Fig. 11.6 Transverse section of maize leaf showing

In C_4 plants, the initial acceptor of CO_2 is **phosphoenol pyruvic acid or PEP**, a 3-carbon compound. It combines with CO_2 in presence of an enzyme **Phosphoenol pyruvate carboxylase (PEPCase)** and forms a C_4 acid, oxaloacetic acid (OAA) This fixation of CO_2 occurs in the cytosol of the mesophyll cells of the leaf. OAA is the first stable product of this cycle and hence the name C_4 pathway.

OAA then travels from mesophyll cells to the chloroplasts of bundle sheath cell where it releases the fixed CO₂. C₃ cycle operates within these cells and this CO₂ immediately combines with RuBP and C₃ cycle continues producing sugars. (See Fig. 11.7).

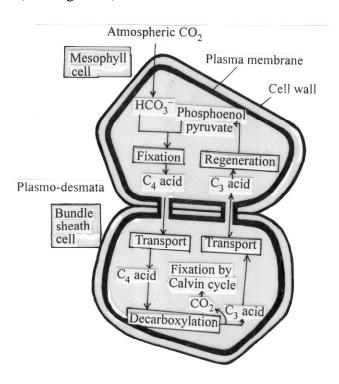

Fig. 11.7 The C4 photosynthetic carbon cycle

- Thus in C_4 pathway of dark reaction, there are two carboxylase enzymes that take part-PEPCase in the mesophyll cells and Rubisco in the bundle sheath cells.
- The differences between C_3 and C_4 plants are tabulated below.

Table 11.3 Difference between C₃ and C₄ Plants

	C ₃ Plants	C ₄ Plants
Carbon dioxide fixation	Occurs once	Occurs twice, first in mesophyll cells, then in bundle sheath cells.
Carbon dioxide acceptor	RuBP, a 5-C- compound	Mesophyll cells. PEP (Phosphoenol Pyruvic acid), a 5C-compound. in the bundle sheath cells-RuBP
Carbon dioxide fixing enzymes	RuBP carboxylase, which is inefficient	PEP caboxylase which is very efficient.
		RuBP carboxylase, works efficiently because carbon dioxide concentration is high.
First product of photosynthesis	A C ₃ acid, PGA	A C ₄ acid, e.g. oxaloacetic acid

Efficiency	Less efficient plotosynthesis than C_4 plants. Yields usually much lower.	More efficient photosynthesis than C ₃ ; plants. Yields usually much higher.

1	INTEXT QUESTIONS 11.2
1.	What is the role of NADP?
2.	Why is dark reaction called so?
3.	What is the role of the enzymes (i) rubisco (ii) PEPCase and where are they present?
1.	Explain Kranz anatomy.
5.	Differentiate between the chloroplasts present in the mesophyll cells and in the bundle sheath cells of the leaf of a C_4 plant.
5.	Why are C ₄ plants more efficient than C ₃ plant?
7.	Name the two sets of reactions in photosynthesis in which light energy is required.

11.6 FACTORS AFFECTING RATE OF PHOTOSYNTHESIS

11.6.1 Factors affecting Photosynthesis

Factor affecting photosynthesis can be divided into two broad categories, the internal and external (environmental)

(i) Internal Factors

1. Chlorophyll: The amount of chlorophyll present has a direct relationship with the rate of photosynthesis because this pigment which is photoreceptive and is directly involved in trapping light energy.

- 2. Leaf age and anatomy: Newly expanding leaves show gradual increase in rate of photosynthesis and the maximum is reached when the leaves achieve full size. Chloroplast functions decline as the leaves age. Rate of photosynthesis is influenced by variation in (i) number, structure and distribution of stomata, (ii) size and distribution of intercellular spaces (iii) relative proportion of palisade and spongy tissues (iv) thickness of cuticle etc.
- **3. Demand for photo synthate :** Rapidly growing plants show increased rate of photosynthesis in comparison to mature plants. When demand for photosynthesis is lowered by removal of meristem the photosynthetic rate declines.

(ii) External Factors

The major external factors which affect the rate of photosynthesis are temperature, light, carbondioxide, water, mineral elements etc.

Concept of limiting factors: When a process is affected by various factors, the rate of the process depends upon the pace of the slowest factor. For example, out of light carbon dioxide and temperature, it is seen that when all three factors are optimum, the rate of photosynthesis is maximum. However of the three factors even if one of the factors become suboptimal and the other factors remain optimal, the rate of the process decline substantially. This known as law of limiting factors or law of minimum shown by Blackman in 1905. It is defined as when a process is conditioned as to its rapidity by a number of separate factors, the rate of the process is limited by the pace of slowest factor.

Light: The rate of photosynthesis increases with increase in rate of intensity of light or rate of photosynthesis is directly proportional to light intensity. Except on a cloudy day light is never a limiting factor in nature.

At a certain light intensity the amount of CO_2 used in photosynthesis and the amount of CO_2 produced in respiration are the same. This point of light intensity is known as **compensation point**.

Wavelength of light affects rate of photosynthesis. Red light and to some extent blue light has an enhancing influence on photosynthesis (See action spectrum).

Temperature : Very high and very low temperature affect the rate of photosynthesis adversely. Rate of photosynthesis will rise with temperature from 5° - 37° C beyond which there is a rapid fall, as the enzymes involved in the process in the dark reaction get inactive at the temperature. Between 5° - 35° C, with every 10° C rise in temperature rate of photosynthesis doubles or Q_{10} is 2 (Q = quotient).

Carbon dioxide: Carbon dioxide being one of the raw materials for photosynthesis its concentration affects the rate of photosynthesis markedly. Because of its very low concentration (0.03%) in the atmosphere, it acts as limiting factor in natural photosynthesis. At optimum temperature and light intensity, if carbon dioxide supply is increased the rate of photosynthesis increases markedly.

Water: Water has an indirect effect on the rate of photosynthesis. Loss of water in the soil is immediate the felt by the leaves which close down the stomata thus

MODULE - 2

Forms and Function of Plants and Animals

Notes

rms and Function of ints and Animals

Photosynthesis

hampering the absorption of CO_2 from the atmosphere. This causes decline in photosynthesis.

Mineral elements : Some mineral elements like copper, manganese, chloride etc. which are components of photosynthetic enzymes or magnesium as a component of chlorophylls also affect the rate of photosynthesis indirectly by affecting the synthesis of photosynthetic enzyme and chlorophyll respectively.

11.7 CHEMOSYNTHESIS

Chemosynthesis

When plants utilise light energy to reduce carbon dioxide to carbohydrates, they are called photosynthetic autotrophs. There are organisms which can utilise chemical energy released during biological oxidation of certain inorganic substances to reduce carbon dioxide to carbohydrate. These bacteria are called **chemosynthetic autotrophs.**

This is found in many colourless bacteria and because they use chemical energy to reduce carbon dioxide, this process of carbohydrate synthesis is known as **chemosynthesis**.

Chemosynthesis may be defined as "the method of carbon assimilation when the reduction of CO_2 is carried out in darkness, utilising the energy obtained from oxidations of inorganic substances.

The common chemosynthetic forms are:

- (i) Nitrifying bacteria. Nitrosomonas oxidises NH₃ to NO₂
- (ii) Sulphur bacteria
- (iii) Iron bacteria
- (iv) Hydrogen and methane bacteria

Differences between photosynthesis and chemosynthesis

Chemosynthesis			Photosynthesis		
1.	It occurs only in colourless aerobic bacteria	1.	This process occurs in green plants including green bacteria.		
2.	During this process CO ₂ is reduced to carbohydrates without light and chlorophyll.	2.	CO ₂ and H ₂ O are converted into carbohydrates in the presence of light and chlorophyll.		
3.	Here chemical energy released during oxidation of inorganic substances is used up to synthesise carbohydrates.	3.	Light energy is converted into chemical energy and stored in the form of carbohydrates.		
4.	No pigment molecule is involved and oxygen is not evolved.	4.	Several pigments are involved and oxygen is evolved as a byproduct.		
5.	No photophosphorylation takes place.	5.	Photophosphorytion takes place i.e. ATP is produced.

WHAT YOU HAVE LEARNT

- Green plants are capable of synthesizing carbohydrates from CO₂ and H₂O in the presence of light, by the process of photosynthesis.
- During photosynthesis 'light energy', which is captured by the photosynthetic pigments (chlorophyll, carotenoids and xanthophylls) present in the chloroplasts, is converted into chemical energy.
- Photosynthesis in general is expressed by the following equation:

$$6\text{CO}_2 + 12\text{H}_2\text{O} \xrightarrow{\text{Chlorophyll}} \text{C}_6\text{H}_{12}\text{O}_6 + 6\text{H}_2\text{O} + 6\text{O}_2$$

- Photosynthesis comprises two sets of reactions:
- Light reactions: which take place in grana only in the presence of light.
- Dark reactions: Which occur in the stroma of chloroplast and are independent of light.
- Light energy is used for splitting of water, and actual reduction of CO₂ takes place in the dark reaction.
- Light reaction occurs in two functional units photosystem-I and photosystem-II.
- During light reaction phosphorylation of ADP to ATP may occur in two ways, cyclic and non-cyclic.
- During dark reactions CO₂ is accepted by Ribulose biphosphate (RuBP) and the first stable product. 3-PGA (3 phosphoglyceric acid) is formed, which by further cyclic reactions (Calvin Cycle) leads to the formation of carbohydrates as well as in regeneration of RuBP.
- In C₄ plants like maize, jawar, bajra, the primary acceptor of CO₂ is in mesophyll cells and the first detectable product of dark reaction is oxaloacetic acid (OAA), whereas in the bundle sheath cells CO₂ fixation occurs viz. Calvin cycle.

MODULE - 2

Forms and Function of Plants and Animals

Notes

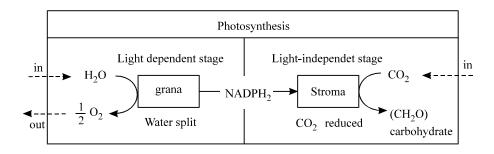

rms and Function of ints and Animals

Photosynthesis

- Leaf anatomy of C₄ plants is known as "Kranz anatomy" and is characterized by the presence of a sheath of parenchyma cells around a vascular bundle (bundle sheath). Cells of this sheath have larger chloroplasts which lack grana and are filled with starch grains. In contrast mesophyll cells contain chloroplasts which are smaller but have well developed grana.
- Rate of photosynthesis is influenced by (i) environmental factors such as light, temperature, carbon dioxide concentration and water, and (ii) internal factors which include age of leaf, chlorophyll content and leaf anatomy.

A SUMMARY OF PHOTOSYNTHESIS

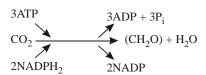

Light-dependent stage

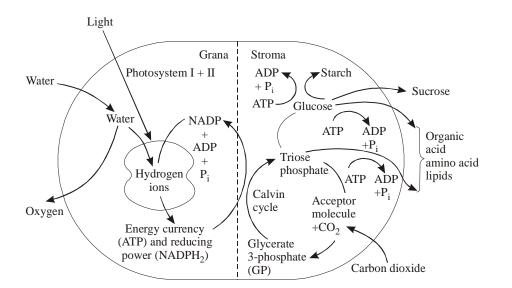

- occurs in the thylakoid membranes of the grana
- largely a photochemical change, requiring light energy
- light energy is converted to chemical energy in the form of ATP and NADPH₂; water is split into hydrogen and oxygen; hydrogen is combined in NADPH₂; oxygen gas is released as a byproduct
- chlorophylls are grouped together in units of about 300 molecules (known as photosystems); two types exist, photosystems I and II
- light energy absorbed by the photosystems causes electrons from chlorophyll to be raised to a high energy level and to pass to NADPH₂; ATP is generated; water is split and provides the electrons to the photosystem and the hydrogen for NADPH₂ production:

$$\begin{array}{ccc} 2H_2O + 2NADP & \underbrace{Light}_{Chlorophyll} & O_2 + 2NADPH_2 \\ \\ ADP + P_i & \underbrace{Light}_{Chlorophyll} & ATP \text{ (considerable, but variable amount)} \\ \end{array}$$

Light independent stage

- occurs in the stroma
- a series of biochemical changes, each reaction catalysed by an enzyme
- carbon dioxide is converted to compounds such as carbohydrates (with the chemical energy of ATP and NADPH2); the reactions of the light-independent stage are known as the Calvin cycle
- carbon dioxide is combined with ribulose bisphosphate (the acceptor substance) and the product splits instantly into two molecules of glycerate 3-phosphate (GP, the first product of photosynthesis)
- GP is reduced to a three-carbon sugar, triose phosphate; then, in a series of reactions, the acceptor molecule is regenerated and sugars, starch and other substances are formed from triose phosphate:

- 11.2 1. NADP acts as an electron acceptor and gets reduce the NADPH₂.
 - 2. It is called dark reaction because it is independent of light i.e. can occur both in light and in dark.
 - 3. (i) Rubisco is a part of C₃ cycle and combine with CO₂ to produce a C₃ compound called PGA.
 - (ii) PEPCase is a part of C_4 path way and combines with CO_2 to form a C_4 compound called OAA.

Rubisco is present in the mesophyll cells of C3 plants and in the bundle sheath cell of C_4 plants.

PEPCase is only found in mesophyll cells of C_4 plants.

- 4. See text
- 5. See text
- 6. C₄ plants have no photorespiration and thus there is no loss of carbon dioxide.
- 7. (i) Photolysis of water
- 11.3 1. leaf age, chlorophyll content, leaf anatomy (size internal structure, stomatal distribution)
 - 2. See text
 - 3. Nitrosomonas
